Abstract Eradication aims at eliminating populations of alien organisms from an area. Since not all eradications are successful, several factors have been proposed in the literature (mainly by referring to case studies) to be crucial for eradication success, such as infestation size or reaction time. To our knowledge, however, no study has statistically evaluated which factors affect eradication success and attempted to determine their relative importance. We established a unique global dataset on 136 eradication campaigns against 75 species (invasive alien invertebrates, plants and plant pathogens) and statistically tested whether

the following factors, proposed by others were significantly related to eradication success: (1) the reaction time between the arrival/detection of the organism and the start of the eradication campaign; (2) the spatial extent of the infestation; (3) the level of biological knowledge of the organism; and (4) insularity. Of these, only the spatial extent of the infestation was significantly related to the eradication outcome: local campaigns were more successful than regional or national campaigns. Reaction time, the level of knowledge and insularity were all unrelated to eradication success. Hence, some factors suggested as being crucial may be less important than previously thought, at least for the organisms tested here. We found no differences in success rates among taxonomic groups or geographic regions. We recommend that eradication measures should generally concentrate on the very early phase of invasions when infestations are still relatively small.

Keywords Eradication success · Invasive species · Contingency planning · Pest Risk Analysis · Invasive species management · Biological invasions

Introduction

Despite increased research efforts about the impact of invasive species (Winter et al. 2009; Vilà et al. 2009; Nentwig et al. 2010), their economic costs (Kettunen et al. 2009), and intensive exploration of management

options (Hulme 2006, 2009; Pyšek and Richardson 2010), little is known about how environmental settings, species traits and other contingent factors affect the outcome of management actions against invasive species. Key management options for invasive species include: prevention, eradication, containment, and various forms of mitigation (Pyšek and Richardson 2010; Shine et al. 2010). Among these, eradication represents the ultimate course of action, but often also the most expensive solution. Eradication is the application of control measures aiming at extirpating an entire population of a pest from an area (FAO 2007) or from a management unit (Pyšek and Richardson 2010). Recently, there has been a renewed interest in eradicating invasive species, following a period when the prevailing view was that the elimination of a pest population was very seldom achievable (Simberloff 2009; Pyšek and Richardson 2010).

Much research is being published suggesting decision-tools for an efficient application of control measures in specific situations such as the infestation of the gypsy moth (*Lymantria dispar*) in the United States (Bogich et al. 2008), the campaigns against the brown rat (*Rattus norvegicus*) in South Georgia, Southern Ocean (Robertson and Gemmell 2004) or against bitterweed (*Helenium amarum*) in Australia (Rout et al. 2009a, b; Regan et al. 2006). However, these are case-specific decision-aid tools that do not allow drawing general conclusions as to which factors are important for eradicating a pest population.

The difficulty is that it is not always clear at first what is the most appropriate way to react to a new pest incursion. When responsible authorities are confronted with a new infestation, they need to know which factors are most important for enhancing the likelihood of eradicating the unwanted organism so that an appropriate control strategy can be designed and implemented. A number of reviews of eradication campaigns has been published in the last two decades, comparing the outcomes for various taxonomic groups based on descriptive case studies (Clout and Veitch 2002; Simberloff 2003b, 2009; Myers et al. 2000; Genovesi 2007; Bomford and O'Brien 1995), or assessing taxonomic groups separately, such as plants (Mack and Lonsdale 2002; Rejmánek and Pitcairn 2002; Simberloff 2003a), mammals (Courchamp et al. 2003), moths (Brockerhoff et al. 2010), invertebrates (Dahlsten and Garcia 1989), plant pathogens (Sosnowski et al. 2009) or vertebrates and plants (Genovesi 2005).

All of these reviews drew general conclusions as to why eradication campaigns fail or succeed based on evidence from the case studies they reviewed and suggested a number of factors relating to eradication success. However, evidence from case studies can be equivocal as to which factors may be relevant for eradication success. There is thus a need to take a quantitative approach that assembles data on as many cases as possible, including both successful and failed eradications. By applying statistical analyses it may be possible to identify general principles or critical factors associated with successful eradication campaigns. In the following, four of the success factors proposed in the literature which can be quantified and therefore be subject to statistical analyses are discussed and hypotheses formulated for subsequent analyses.

Several authors consider that a rapid response, following the first detection of the invasive organism, is crucial for eradication success, because it prevents the organism from spreading (Clout and Veitch 2002; Simberloff 2003b, 2009; Myers et al. 2000; Genovesi 2007; Bomford and O'Brien 1995). It is also assumed that small and isolated populations are easier to eradicate, and that a rapid reaction prevents further population growth and spread (Liebhold and Bascombe 2003; Clout and Veitch 2002; Mack and Lonsdale 2002; Brockerhoff et al. 2010). As a consequence, it is expected that infestations occupying a small area are easier to eradicate, because measures can be applied more thoroughly and are more likely to be cost effective at smaller scales. Brockerhoff et al. (2010) examine this type of approach for six moth species, all forest pests in New Zealand and found a strong positive relationship between the size of the affected area and eradication costs. Furthermore, Allee effects favoring eradication might be stronger if the pest population and the area it occupies are still small (Vercken et al. 2011; Liebhold and Bascombe 2003).

Another argument often put forward is that detailed biological knowledge concerning an organism is needed in order to design appropriate control measures; the target species must be studied well enough to suggest vulnerabilities (Simberloff 2009). Examples are the use of super-Judas goats (i.e. the release of sterilized and hormone-treated female goats) to eradicate goats from the Galapagos Islands or the development of pheromone lure traps against the sea lamprey (*Petromyzon marinus*) in the Great Lakes (Simberloff 2009). Another example is the eradication

of the painted apple moth (*Teia anartoides*) in New Zealand, where a combination of tactics was used, including the sterile insect technique (Suckling et al. 2007). We assume that understanding the biology of the species translates into better plans to eradicate it. This implies that campaigns with species-specific eradication or contingency plans should be more successful than those following only generic plans.

Many eradications are initiated on islands because it is assumed that eradication campaigns carried out on islands might be more likely to succeed than those on mainland sites (Courchamp et al. 2003). At least for vertebrates, especially mammals, the most notable successes were achieved on isolated island populations (Clout and Veitch 2002; Courchamp et al. 2003). Successful campaigns have also targeted insects on small islands, beginning with the tsetse fly (*Glossina* spp.) campaign on Principe or the screw-worm (*Cochliomyia hoinivorax*) campaign on Curaçao (Simberloff 2008). Eradication of plants from islands appears to be, in quantitative terms, less successful: as illustrated by a review of the outcomes of plant eradication efforts on the Galapagos Islands (Gardener et al. 2010), where of 30 eradication projects covering 23 potentially invasive plant species with limited distributions on four Galapagos Islands, only four were successful (but see Simberloff et al. 2011).

The present study statistically analyzes four factors proposed in the literature (reaction time, the extent of the infestation, the knowledge of the invading species' biology, and whether the campaign was on an island or the mainland) for their association with eradication success. These factors were tested on data of eradication campaigns against invasive alien invertebrates, plants and plant pathogens (bacteria, fungi, and viruses/viroids) that are of economic (e.g. agricultural) but also of ecological importance. Eradication of plant pest populations is most often attempted in the agricultural sector (i.e. the repeated eradication of the Colorado beetle in the United Kingdom; Bartlett 1979). Nonetheless, there is a strong need to improve the decision-making process in plant protection in both economic and ecological environments and especially for newly emerging pest species (Opstal and Sunley 2009). In particular, the following four hypotheses were tested:

- (i) A rapid response to a pest incursion increases the chances of eradication success.
- (ii) Small infestations are easier to eradicate than larger ones.
- (iii) Biological knowledge and a high level of preparedness to react to an incursion increase the chances of eradication success.
- (iv) Island eradications are more likely to succeed than those carried out on mainland areas.

It was also tested, whether there are differences in the eradication success among organisms from different Kingdoms and among biogeographic regions.

Materials and methods

Data collection

The scientific and grey literature was searched for information about eradications of invasive alien invertebrates, plants and plant pathogens, published in scientific publications, eradication reports, other technical reports, pest alerts and online press releases from national plant protection organizations (NPPOs). Information about eradication campaigns is often difficult to obtain from published literature (Simberloff 2009), and the European project PRATIQUE (Baker et al. 2009) provided a unique and unprecedented opportunity to access unpublished (expert) knowledge. Thus national and regional plant protection organizations were important sources of information, and pest managers from NPPOs from Europe, North America, Australia and New Zealand were contacted to provide examples and detailed information about eradication campaigns from their countries.

We collected data on 136 plant pest and weed eradication campaigns from 5 Kingdoms, of which 70 were targeted against invertebrates (belonging to 34 species, mostly insects), 19 against bacteria (six species or subspecies), 13 against fungi (10 species), 18 against plants (18 species) and 16 against viruses/viroids (seven species or subspecies), see Table 1 for a species list. Information from 26 countries, divided into 74 European, 39 American and 23 Australasian campaigns was collated. The campaigns had been launched between 1914 and 2009, with the large majority (71%) being started after 1990 (Fig. 1a). The campaigns were carried out in a variety of habitat types including wetland, grassland, woodland, agricultural, horticultural or domestic habitats and constructed,

industrial or other artificial habitats, see Fig. 1b) for more details. The dataset was dominated by campaigns against organisms in artificial habitats (62%) with 21 campaigns being carried out exclusively in protected

areas (e.g. glasshouses). Most other campaigns were carried out in a variety of different habitat types, including (semi-)natural habitats (Fig. 1b).

A campaign was considered a success if successful eradication of the organism had been officially declared; otherwise it was treated as failure. Campaigns on-going as of December 2009, were also considered as having failed, since successful eradication had not yet been declared. A list of all cases and tested factors is given in Table A1 as Supplementary Material.

Explanatory variables

For each eradication campaign, the following variables, corresponding to the four hypotheses, were considered (see Table 2 for their detailed description).

- (i) *Reaction time*: The time elapsed between the arrival of an organism and the beginning of management measures was counted in months. If the arrival date was not known, the date of first record was taken as starting point.

Fig. 1 Frequency distribution of **a** the starting year of 136 eradication campaigns against invasive alien invertebrates, plants and plant pathogens and **b** the type of habitats affected by these campaigns. Habitat types are following the EUNIS habitat classification by Davies and Moss (2003; <http://eunis.eea.europa.eu/habitats.jsp>): *B*: coastal habitats; *C*:

inland surface waters; *D*: mires, bogs and fens; *E*: grasslands, and lands dominated by forbs, mosses or lichens; *G*: woodland, forest and wooded land; *H*: inland unvegetated or sparsely vegetated habitats; *I*: regularly or recently cultivated agricultural, horticultural and domestic habitats (including glasshouses); *J*: constructed, industrial and other artificial habitats

Table 2 Description of dependent variable, explanatory variables (potential success factors for plant pest and weed eradications) and random factors

<i>Dependent variable</i>	
1) Successful eradication	The eradication campaign was successful, which was confirmed by surveys over a time period relevant for the life-cycle of the organism, the campaign stopped, N = 66
0) Failed eradication	All other campaigns, N = 70
<i>Explanatory variables (potential success factors)</i>	
(i) Reaction time	The time elapsing between the arrival (or detection) of the organism and the start of the eradication campaign, counted in months
(ii) Size of infested area	
(1) Local	One rather small, isolated infestation focus, N = 51
(2) Regional	A larger area, but never the entire country, was affected including more than one and up to ten infestation foci, N = 32
(3) National	A campaign in an entire country, usually including more than ten infestation foci. For campaigns in the United States and Canada, states or provinces were classified as “national”, N = 44
(4) International	A campaign involved several countries (or states or provinces in the USA and Canada), the number of infestation foci is irrelevant, N = 9
(iii) Biological knowledge and preparedness to act	
(0) None	Information about the species and possible management measures were collected and evaluated only after the incursion, N = 16
(1) Low	Pest alerts, pest notices or similar information were available when the pest was detected, N = 56
(2) Medium	A Pest Risk Analysis for the species or a generic contingency plan was available when the pest was detected or the pest was well known and control experience existed, N = 25
(3) High	A contingency plan against the species was available when the pest was detected, or a precise plan to eradicate the pest was mentioned, N = 39
(iv) Insularity	
Island	Eradication on an island (including New Zealand), N = 40
Mainland	Eradication on a continent, N = 96
<i>Random factors</i>	
Kingdom	Latin name of taxonomic Kingdom
Name	Species name
Biogeographic region	Name of the continent the eradication took place

(ii) *Infestation size*: To account for the spatial extent of an eradication campaign, a semi-quantitative spatial variable at four levels was introduced.

- 1) Local; one small, isolated infestation focus, for example a finding in an individual glass-house, a crop field, a nursery or on a group of trees.
- 2) Regional; eradication measures taken at a regional scale, but within a country, including more than one and up to ten local infestation foci.
- 3) National; the campaign was addressed against an organism across an entire country, including more than ten local infestation foci. For campaigns in the United States and Canada,

- measures affecting an entire state or province were also classified as “national”. This classification was chosen assuming that campaigns within one country/state/province should be easier to manage than international campaigns because they largely fall under one jurisdiction.
- 4) International; if several countries (or states or provinces in the case of the USA and Canada) were collectively managing an organism.

While this categorization of scale was easily derived from the description of the situation in the literature, a more precise quantitative measurement of the infestation area (in km²) was rarely available.

(iii) *Biological knowledge and preparedness to act*: As a measure of the level of biological knowledge, the type of documented information available at the moment of the infestation was ranked, assuming that simply having a pest notice or fact sheet would be less informative than an entire Pest Risk Analysis (PRA; FAO 2004) and that a PRA would be less informative than a detailed contingency or eradication plan. It was also assumed that different types of documentation will translate into different levels of preparedness of authorities to appropriately react to an infestation: Contingency or eradication plans would indicate a higher level of preparedness than a PRA or a pest notice, which both usually do not detail pest risk management measures. The degree of knowledge about the species and the readiness of authorities to eradicate an incursion were thus ranked as follows:

- 0) No knowledge/preparedness; information about the species and possible management measures were collected and evaluated only after the incursion.
- 1) Low knowledge/preparedness; pest alerts, pest notices or similar information were available when the pest was detected, but neither a PRA nor a contingency plan were available at that incursion.
- 2) Medium knowledge/preparedness; a PRA for the species or a generic contingency plan on how to react to an infestation in general was available at the incursion.
- 3) High knowledge/preparedness; a species-specific contingency/eradication plan was available at the incursion.

(iv) *Insularity*. It was distinguished whether a campaign was carried out on an island (including New Zealand) or a continent.

Reaction time, spatial extent and knowledge/preparedness were coded as numerical variables, while insularity was a factor in the model.

Analyses

General approach

The relationship between the four factors and eradication success was tested with Generalized Linear

Mixed Models (GLMM; Bolker et al. 2009). We used the function *glmer* from the R package lme4 (version 0.999375-28, Bates et al. 2008). The outcome of each campaign (success/failure) served as the dependent variable and the factors expected to affect the outcome were included as fixed factors: (i) “reaction time”, (ii) “spatial extent”, (iii) “biological knowledge & preparedness” and (iv) “insularity”.

To allow direct comparisons of their relative importance, all numerical variables (i, ii, iii) were scaled prior to the analyses, using the function *scale* from the R package base (version 2.8.1, R Development Core Team 2008). Collinearity between the success factors was low (Spearman rank correlation coefficients, all $r < 0.3$; Zuur et al. 2009).

The outcomes of campaigns against related species can not be considered as independent, because they are likely to share similar characteristics (Manchester and Bullock 2000). Likewise, eradication campaigns in the same biogeographic region may have similar, i.e. dependent outcomes. We accounted for this by including the taxonomic Kingdom of the organism (Animalia, Bacteria, Fungi, Plantae and viruses) and the biogeographic region in which the campaign was conducted (America, Australasia and Europe) as random factors in the models. Additionally, the outcome of eradication campaigns directed against the same pest species can be expected to be related due to intrinsic characteristics of the species concerned. We corrected for this non-independence by including the species as a random factor, nested within Kingdom.

Model selection

Model selection for ecological inference was done in an information theoretic framework (Burnham and Anderson 2002). In a first step, the random part of the model was chosen (Zuur et al. 2009). For that, the AIC of models with all possible combinations of random factors were compared (i.e. no random factor, only species, only Kingdom, only biogeographic region, species nested within Kingdom, species and biogeographic region, Kingdom and biogeographic region, and species nested within Kingdom and geographical region). Each of these models included all four fixed effects. The structure of the random effects of the best-fitting model, i.e. the one with the lowest AIC, or, if $\Delta AIC < 2$, the most parsimonious model was chosen for further analysis (Zuur et al. 2009).

After the random part was chosen, the fixed factors that best explained variation in eradication success were determined. For that, the AIC of models with all possible combinations of the four fixed factors were calculated. All models conforming to two rules were selected for ecological inference (Richards 2008): First, all models with a ΔAIC value ≤ 6 were selected for parameter estimation. This threshold of 6 is much higher than the widely-accepted rule-of-thumb of selecting all models with a ΔAIC value ≤ 2 proposed by Burnham and Anderson (2002), but it recently has been demonstrated that the most parsimonious model, defined as the one with the lowest expected Kullback–Leibler distance, being a measure of the mean discrepancy between the model and the unknowable truth, may be missed otherwise (Richards 2005). As a second rule, a model was only selected if its AIC value was less than the AIC value of all the simpler models within which it is nested in order to avoid selecting overly complex models (Richards 2008). The reasoning for this is that if an additional parameter provides little or no increase in model fit, then the more complex model with the additional parameter will have a ΔAIC -value less or equal to 2 to the simpler model; thus the more complex model fits the data equally well as the simpler model. However, in such cases the more complex model with the additional parameter should not be considered for ecological inference, since nothing is explained by the additional complexity (Burnham and Anderson 2002; Richards 2008).

Finally, the values of all four parameters were estimated by model averaging among the set of candidate models chosen by model selection (function `modavg` from the package `AICcmodavg`, version 1.18 in R; Mazerolle 2011). A parameter can be considered as having a significant effect if the confidence interval does not include zero.

Results

Considering each case as independent, about half of the eradication campaigns (49%) were declared as successful in terms of eliminating the pest from the targeted area.

There were no obvious differences in the eradication success among Kingdoms (Fig. 2a) or biogeographic regions (Fig. 2b). This was supported by

Fig. 2 Mean success rate of eradication campaigns against invasive alien invertebrates, plants and plant pathogens, across **a** five taxonomic Kingdoms and **b** three biogeographic regions. Pseudo-replication is corrected for by calculating the average success rate for each species. Depicted are the means of these species-averages for each Kingdom or biogeographic region, respectively. Animalia = invertebrate animals

logistic regressions of the eradication success with Kingdom or biogeographic region as explanatory variables and the species as random factor (analysis of deviance; Kingdom: $\chi^2 = 4.58$, d.f. = 4, $P = 0.333$, biogeographic region: $\chi^2 = 3.50$, d.f. = 2, $P = 0.174$). It was also tested if the taxonomic Kingdom or the biogeographic region explained a significant proportion of variation in the data by including them as random factors in models with all other explanatory variables. However, all models including Kingdom or biogeographic region fitted the data significantly worse according to the AIC ($\Delta\text{AIC} > 2$) than a model with only the species as random factor. Thus, only species identity was kept as random factor in the following model selection procedure.

Eleven of the 16 fitted models had a ΔAIC -value ≤ 6 (Table 3); the other models were discarded for ecological inference according to the first rule of model selection. The best-fitting model (m2)

contained only infestation size to explain eradication success (Table 3). The seven next best-fitting models all also contained infestation size plus additional explanatory variables (Table 3). They were discarded from ecological inference according to the second rule of model selection, because they represent extensions of a simpler model (m2) and had a worse fit. Apart from the best-fitting model (m2), only three other models were retained for ecological inference: a model with no explanatory variable (m1), and models with either only the level of preparedness (m5) or the reaction time (m4; Table 3). However, these latter three models all had ΔAIC -values >4 and were thus not well supported (AIC weights $\leq 3\%$; Table 3). Parameter averaging among the four retained models (m2, m1, m4 and m5) revealed that only the effect of infestation size was significantly different from zero (model-averaged estimate = -0.56 ; 95% unconditional confidence interval of the scaled estimate: $-0.14, -0.98$); confidence intervals for the level of preparedness ($0.66, -0.16$; average = 0.25) and for the reaction time ($0.23, -0.57$; average = -0.17) included zero. Insularity never was in a model

considered for ecological inference. Thus, infestation size was the only parameter that received strong support to affect eradication success. The relationship between the four tested potential factors for eradication success and the outcome of campaigns is depicted in Fig. 3.

Discussion

Of all stipulated success factors tested here, only the extent of the infestation was important for eradication outcome. Not unexpectedly, local infestations were easier to eradicate than regional or national ones. This is in accordance with a study of plant eradications in California, where the eradication of exotic plant infestations smaller than one hectare was usually possible, but the likelihood of eradication declined rapidly with increasing area, making the eradication of species occupying $>1,000$ ha very unlikely, given the resources typically committed to such operations (Rejmánek and Pitcairn 2002). Eradications at the local level might be easier because the infestation is

Table 3 Results of model selection

× Factors present in the models. Models are ordered according to their AIC values

ΔAIC : Difference between the AIC of the best-fitting model and the current model. *AIC weight*: The Akaike weights; these measures indicate the level of support (i.e. weight of evidence) in favor of any given model being the most parsimonious among the candidate model set. * Models selected for parameter estimation

Fig. 3 Mean success rates of eradication campaigns against invasive alien invertebrates, plants and plant pathogens, depending on **a** reaction time in months, **b** the infestation size at four levels, **c** four different levels of biological knowledge and preparedness to react and **d** whether the eradication took place

on an island or the mainland. Pseudo-replication is corrected for by calculating the average success rate for each species. Depicted are the means of these species-averages for the four potential success factors

isolated and delimitation is therefore more straightforward. Small-sized populations may not yet have become fully established, may not have spread and may be more prone to Allee effects than larger populations (Liebholt and Bascompte 2003). For example, a recent study found evidence that a critical patch size exists across the invasion front of the European gypsy moth (*Lymantria dispar*) in the United States, below which pest populations cannot persist due to Allee effects (Vercken et al. 2011). Such a mechanism could be useful for invasive species management (Tobin et al. 2011), because it implies that not every single individual of a target population needs to be removed, the population only needs to be reduced below a critical patch size when extinction is inevitable. However, it is yet unclear if the concept of the critical patch size is applicable to many species. A recent study on Allee effects during establishment of

natural populations suggests that strong Allee effects, a prerequisite of critical patch size, are rare in many animal taxa (Duncan, Blackburn, Rossinelli & Bacher, unpublished data). In addition, targeting large infestations is more resource-demanding, hence eradicating a pest at the regional or even the national level might only be possible with a huge investment of resources (Brockhoff et al. 2010; Rejmánek and Pitcairn 2002). The importance of the size of the infestation for eradication success suggests that eradication measures should concentrate on the early phase of the invasion when infestations are still relatively small. This also highlights the importance of delimiting the infestation quickly after its discovery, in order to have a solid basis for decision-making and investing the appropriate efforts in surveillance and control measures (Panetta and Roger 2005; Panetta 2007). As pointed out by Panetta and Lawes (2007), a

fundamental criterion for evaluating eradication success is an accurate delimitation of an invasion (defined as the determination of its full spatial extent), because unless the invasion has been delimited, undetected infestations will continue to expand and give rise to additional foci of infestation. Nevertheless, eradication success at the national level is not impossible: In our study, 32% of national campaigns were successful.

Eradications on islands were not more successful than those on the mainland. Hence for plant pests and weeds at least, eradication chances seem equal on mainland and on island sites and the actual infestation size is of higher importance than insularity.

As for reaction time and the level of preparedness, it might not be the time or the contingency plan itself that matter, but rather the degree of implementation of the plan. For instance, in the campaigns in our dataset, authorities usually reacted quickly (74% within the first year), but such campaigns were not more likely to succeed than those with slow reaction times. The lack of any relationship between the level of biological knowledge and the outcome of the campaign might mean that having a contingency plan is not in itself enough for successful eradication or does not fully reflect the level of knowledge available. Hence, using the existence of a PRA or a contingency/eradication plan as an indicator for available knowledge might be too coarse a variable, because aspects of the ecology of species and management actions are mixed. We conclude that having a contingency or eradication plan is no guarantee for success, nor should lack of knowledge about the species be an excuse for inaction. In a next step, we suggest to evaluate the degree of implementation of a contingency or eradication plan: Having the authority to enforce cooperation and dedicated project leaders, thus insuring that an eradication plan is implemented, are also key for success (Simberloff 2009). However, indices to measure the degree of implementation are still missing and could be developed in collaboration with economists.

An average success rate of 49% to eradicate plant pests and weeds may appear high, but it supports Simberloff's argument that eradication success may often go unnoticed while failures are well publicized (Simberloff 2009). One could argue that the high success rate might be due to the dominance in the dataset (62%) of mainly agricultural pests that were repeatedly successfully eradicated, such as the Colorado potato beetle (*Leptinotarsa decemlineata*)

(Bartlett 1979), several fruit flies species or the bacterial and virus diseases in our dataset (Table 1). Many of these infestations occurred in artificial or protected environments, and as such may have been easier to eradicate than invasive species occupying natural habitats. However, compared to other eradication databases the success rates reported here do not seem high. The Global Island Invasive Vertebrate Eradication Database (www.islandconservation.org; accessed Oct. 2011) lists 952 attempts of vertebrate eradications of which 784 were classified as successes and only 88 as failures (89.9% successes). Howald et al. (2007) report similarly high success rates varying between 95% (Norway rats, *Rattus norvegicus*) and 81% (house mice, *Mus musculus*) for rodent eradication attempts on islands. However, for weed eradications on the Galapagos islands success rates of only 13% have been reported (Gardener et al. 2010). The present study is the first to quantitatively analyze eradication campaigns against plant pests and weeds; similar analyses on taxonomic groups not included here are currently lacking, but they would be necessary to judge if patterns found here are general. For example, it might be worthwhile to test economic and ecological pests separately. Such a restriction of the target system will reduce potential sources of variation due to differing habitat properties or heterogeneous stakeholder interests and allow gaining deeper insights into the role of factors determining eradication success.

The lack of support for an effect of reaction time, the level of knowledge/preparedness and insularity in our study does not necessarily mean that these factors are never relevant for eradication success. It could be argued that their non-significance is caused by the limited size of the dataset or by a large variation within the data. However, two expected sources of variation (differences due to taxonomy and biogeographic regions) had no significant effect on eradication success.

While no differences were found in eradication success between the main biogeographic regions Europe, America and Australasia, it can still be expected that a country's invasive species policy and the amount of resources it invests in this issue affect eradication success. We did not attempt to capture such socioeconomic aspects of eradications in this study, although we are aware of their potentially critical importance for an efficient invasive species

management (Keller et al. 2009). Optimal resource allocation in prevention (surveillance) and control have been modeled by several authors and for different organisms and ecosystems such as the Zebra mussel (*Dreissena polymorpha*) (Leung et al. 2002) or orange hawkweed (*Hieracium aurantiacum*) (Hauser and McCarthy 2009). A recent review found that a management objective explicitly considering both costs and damages is most appropriate for determining economically optimal strategies, but faces challenges due to uncertainty (Epanchin-Niell and Hastings 2010). Instead of capturing a country's invasive species policy or optimal resource allocation, we attempted to collate information about actual eradication costs (monetary costs and manpower involved). However, this kind of information was available in only 35% (monetary costs) and 15% (manpower) of the cases, and had thus to be discarded from the quantitative analysis. This is a serious shortcoming in our knowledge of eradication projects. In the absence of more precise figures, an economic indicator like Gross Domestic Product of the country in which a campaign was carried out as a proxy for funding efforts could be used instead. Nonetheless, we encourage pest managers to thoroughly collect and communicate eradication costs for future research and thus also provide a basis for future cost-benefit analyses.

Acknowledgments We thank Richard Baker, Andrea Battisti, Marc Kenis, Nico van Opstal, Marc Cadotte and four anonymous reviewers for helpful comments on previous drafts of this paper and Sylvie Augustin, Peter Baufeld, Annemarie Breukers, Eckehard Brockerhoff, Mark Bullians, Louise Dumouchel, Dominic Eyre, Ben Gasman, Salla Hannunen, Katrin Kaminski, Oľia Karadjova, John Kean, Hella Kehlenbeck, William Larkin, Lorenzo Marini, Sharon Matthews-Berry, Anthemis Melifronidou, Petra Mueller, Melanie Newfield, Mary Orr, Grant Telford, Sunil Singh, Edoardo Petrucco Toffolo, Olivier Pruvost, Serge Quirici, Peter Reed, Cécile Robin, Muriel Suffert, Dirk Jan van der Gaag, Peter Whittle, and Annie Yart for providing information on eradication campaigns. Work on this paper was supported by the European Commission under grant agreement number KBBE-212459, 7th Framework Programme, project PRATIQUE: Enhancement of Pest Risk Analysis Techniques. V.J., J.P. and P.P. were further supported by grants 206/09/0563, 504/11/1028 (Czech Science Foundation), AV0Z60050516, IAA600050811 (Academy of Sciences of the Czech Republic), MSM0021620828 and LC06073 (Ministry of Education, Youth and Sports of the Czech Republic). P.P. acknowledges support from a Praemium Academiae award from the Academy of Sciences of the Czech Republic.
